Abstract

Introduction: This study was conducted in order to evaluate the adaptation control on VAP prevention bundle adaptation control in terms of VAP speed, length of stay at hospital and adaptation of healthcare staff to bundle application.

Method: The data of the study, which was conducted in cross sectional pattern on controlled and uncontrolled groups for ten months each, was gathered via Introductory Features Form, VAP Prevention Bundle Application List and VAP Prevention Bundle Control List. Gathered data was presented in numbers, percentages, averages and standard deviations. The data was analyzed via chi square test, Mann-Whitney U and Kruskal-Wallis tests.

Results: It was found out that the length of stay at hospital for controlled group (X=11.41±12.29) is fairly shorter than of uncontrolled group (X=31.41±36.41); and it was also found out that, in comparison with the controlled group (4.7%) the VAP development rate is higher with the uncontrolled group (19.6%) and the difference in percentages is statistically meaningful. With the uncontrolled group the VAP speed is measured as 7.12 ventilator days while the time is 4.14 with the controlled group; and difference in time spent on mechanical ventilator is found to be statistically highly meaningful. In this study, it was found out that the adaptation rate of doctors and nurses working at ICUs to ventilator bundle are 69.89%.

Conclusion: In accordance with the gathered data, it was determined that, controlled and uncontrolled groups have similar characteristics in terms of introductory features; although the adaptation rate with controlled group is lower than the average numbers in literature, while the VAP rate and speed is higher with the uncontrolled group, these numbers decrease to statistically meaningful levels with the controlled group. In our study it was observed that, in comparison with the uncontrolled group, the length of time spent at hospital and on mechanical ventilator is statistically shorter with the controlled group.

Introduction

Ventilator-associated pneumonia (VAP), which is defined as pneumonia that occurs within 48 hours after intubation with patients, who did not have pneumonia prior to intubation, receiving mechanical ventilation during the intubation, increases risk of mortality, days spent on mechanical ventilator, length of time spent at hospital and cost of care in critically ill patients [1-3]. VAP is a complicated condition in terms of diagnosis and treatment, and it is also a priority condition that should be prevented in clinical settings [4,5]. For this reason, prevention of VAP in ICUs is considered as an important practice for patient safety and an indication of health care quality. The incidence rate of VAP varies according to the type of ICUs, hospital and country. The Centers for Disease Prevention and Control-CDC 2018 has determined the VAP rates as 6 to 10.3/103 ventilator days in adult intensive care units, 7.3 to 103 ventilator days in internal ICUs, and 13.2 to 103 ventilator days in surgical intensive care units. In our country, in National Hospital Infection Surveillance Web of Department of Health 2014 report, the VAP number is calculated as 3467 and 7.6% in 456956 mechanical ventilator days in anesthesiaology - reanimation ICUs [6].

In spite of the guidelines developed recent years, VAP development in ICUs is still a serious issue [7] and extra financial and clinical charge originated by VAP development is an indisputable fact [5]. Nevertheless, it is to our knowledge that only the half of the patients staying at intensive care units are administered with clinically proven, up-to-date VAP preventive treatment [8]. On the other hand, Institute for Healthcare Improvement (IHI) reports that applying only one proven method is not enough to prevent hospital infections, in accordance with recently carried out studies. Therefore, in order to achieve the goals of care and to increase adaptation in standardized applications, the term “care bundle” was put forward in terms of idealized regulations in ICUs. In this manner, idealized ICUs are parts of healthcare institutions which bring VAP risk preventive measurements to forefront [1]. Because, decreasing VAP incidence ratio in intensive care units is regarded as a significant indicator of quality in terms patient safety [5]. In order to get this objective, following strategies such as team work under IHI Ventilator Bundle Guidelines, coordinated multi-discipliner patient visits, determination of daily goals, administration of scientifically proven treatment techniques and removing the mechanical ventilators as soon as possible, many health institutes aim to achieve significant decrease in VAP incidence speed [9].

In accordance with scientifically proven clinical application guidelines, ventilator bundles contribute to the best healthcare service available [1]. Ventilator bundles are groups of approaches which can contribute to recovery process of patients when they are administered on their own, but these approaches bring a lot more success when administered as a whole [1,10]. According to IHI guideline, ventilator bundle must be designed by a multi-discipliner team, and the bundle must be as small and efficient as possible. Ventilator bundle must consist of 3 to 5 scientifically proven applied and preventive paces, each should be able to applied on its own and each must be able to contribute to quality of scientifically proven care method [1,10,11]. In the 100.000 Lives (2006) campaign of IHI, it was reported that VAP did not develop on patients of controlled groups who were staying at 14 different hospitals and administered with ventilator bundles [1]. In their VAP Prevention Guideline (2006), IHI recommended the four approaches of mechanical ventilator bundle as: elevation of bedhead around 30-45°, daily sedation check and fast extubation, peptic ulcer prophylaxis and deep vein thrombosis; in 2010, included daily oral care with chlorhexidine to the list; and in 2012 updated the ventilator bundle to its current form [1,10].

In the literature, there are numerous international [4,12-17] and national [18-20] studies which were carried out in order to find out the efficiency of application of ventilator bundle on VAP development speed. In these studies, it was proven that it is possible to decrease the VAP development speed significantly and it is even possible to fully prevent VAP development via application of ventilator bundle. In our country, there are two proficiency and a PhD thesis which focus on the issue [18-20]. Yıldız [18] evaluated adaptation of anesthesiology and neurology ICUs staff to 5 approaches ventilator bundle which was updated by IHI in 2012. In Yıldız's study, it was found out that full adaptation to updated ventilator bundle was 30.5%. VAP did not develop with patients of full adaptation and there is statistically significant correlation between ventilator bundle adaptation and VAP development [18]. In another study, which was carried out by Sungur [19] in order to find out the success of eight approaches ventilator bundle that applies elevation of bedhead around 30-45°, endotracheal pressure of 20-25 cmH₂O, subglottic aspiration, closed system aspiration, chlorhexidine oral care, sedation pause, deep vein thrombosis prophylaxis and peptic ulcer prophylaxis, it was found out that no significant decrease in VAP surveillance was observed prior to and during the application of ventilator bundle. In a study carried out by Kılıncalp [20], it was found out that, with 92.3% adaptation to nine approach ventilator bundle (peptic ulcer and deep vein thrombosis prophylaxis, elevation of bedhead, subglottic aspiration, oral care, removal of ventilator, aseptic application of aspiration, monitoring of cuff pressure, cleaning the ventilator parts/prevention of liquid accumulation) VAP speed dropped from 14.7/103 days to 3.28/103 days.

Aim of the ventilation bundles is practicing clinically proven application guidelines, standardization of care techniques and enhancing healthcare approaches. In the literature there are numerous studies that are conducted in order to find out effects of ventilator bundle applications on VAP speed, and the approaches and their numbers differ in accordance with the studies which are mainly carried out by single disciplines [19-26]. Contrary to these mono-discipliner studies, our study was conducted on controlled and uncontrolled groups for 10 months for each by a multi-discipliner team of anesthesiologists, specialists, medical students, nurses, infectious diseases specialists and nurses, academicians and clinic nurses. With our study, we believe that we have contributed to decreasing VAP incidence ratio significantly in the intensive care unit where we conducted our study, shortening the time spent on mechanical ventilator and at hospital, including VAP prevention bundle into the standardized procedures of the institution, and increasing the awareness level of the team, which have conducted the study, on significance of ventilator bundle application.

Objective

This study was conducted in order to evaluate the adaptation of VAP prevention bundle adaptation control in terms of VAP speed, length of stay at hospital and adaptation of healthcare staff to bundle application.

Material and Method

Type of the study

The study is of cross-sectional pattern.

Population and sample

Sample of this study, which was conducted in cross-sectional pattern on controlled and uncontrolled groups for ten months each, includes 94 patients (Uncontrolled group: 51; Controlled group: 43) whose medical needs correspond to aims of the study and willingly took part or allowed to take part in it, and stayed at Intensive Care Unit of Anesthesiology and Reanimation Department of a university hospital from 01.05.2016 to 01.01.2018.

Inclusion criteria

Patients, who (1) are staying at intensive care unit, (2) are 18 or over, (3) stayed at intensive care unit for 48 hours or longer and intubated with mechanical ventilator, (4) were intubated in another service, observed less than 24 hours and transferred to intensive care unit, were included into the study.

Exclusion criteria

Patients, who (1) are diagnosed with pneumonia while hospitalization or transfer to intensive care unit, or were diagnosed with pneumonia longer than 48 hours ago, (2) had oral surgery, (3) are bleeding, can not take antithrombotic treatment and can not be moved, (4) have depressed immune system, currently taking chemotherapeutic agents as immune-suppressive medication or took them within past 30 days, were excluded from the study.

Data Collection Tools

In order to gather data, (1) Introductory Features Form, (2) VAP Prevention Bundle Application List which was designed in accordance with the current literature [4,12-20, 24]and (3) VAP Prevention Bundle Control List were utilized.

Introductory Features Form: This form consists of 11 questions including patient's and companion's first names and family names, age, gender, diagnosis, date of hospitalization, administration date of mechanical ventilation, respiratory condition, date of discharge, number of days spent at hospital, length of time on mechanical ventilation, former clinic and reason of hospitalization.
VAP Prevention Bundle Application List (VAP-PBAL): This list, which is applied to controlled group patients, consists of a chart of 31 days and four questions as follows: first name and family name of the patient, bed number, VAP situation and if developed on which day of the ventilation did the VAP occur. The chart is a medium of documentation which is filled by clinical specialists and nurses for each shift in accordance and adaptation with approaches included into the ventilator bundle.

VAP Prevention Bundle Control List (VAP-PBCL): This list was designed in order to check the adaptation of doctors and nurses to ventilator bundle. The list consists of three parts containing first and family name of the patient, bed number and control date, and a chart application condition of ventilation bundle in accordance with 08-16, 16-24 and 24-08 shifts. The chart is a medium of documentation which is filled by chief doctor and nurse of the department together at 08:30 - 09:00 in the morning after 24 hours of ventilator application.

Application of the study

This study was carried out on controlled and uncontrolled phases for 10 months each. On the first phase, routine applications were carried out in the clinic for ten months. As the routine application, 11 approaches VAP prevention bundle was utilized, which was recommended by infections control committee of the institution. The approaches included in the routine bundle are (1) disinfection of hands before contact with the patient, (2) elevation of bedhead around 30-45°, (3) monitoring of cuff pressure, (4) cleaning the ventilator/ prevention of liquid accumulation, (5) evaluation of aspiration requirements and aspirating the patient with aseptic technique, (6) removing the ventilator, (7) oral care for three times at least, (8) avoiding unplanned ex-tubation and re-intubations, (9) peptic ulcer prophylaxis, (10) deep vein thrombosis prophylaxis, (11) and daily sedation pause. At this phase of the study, doctors and nurses were not inspected but utilizing the identifier form only records were gathered which contains data about VAP development situation, and if developed on which day of the ventilation it occurred.

The second part of the study includes the ten months controlled phase. At this phase, the routine ventilation bundle was reevaluated by study team and redesigned in compliance with IHI’s updated VAP Prevention Guidelines of 2012. The redesigned ventilator bundle consists of 5 approaches; (1) elevation of bedhead around 30-45°, (2) evaluation of daily sedation, (3) peptic ulcer prophylaxis, (4) deep vein thrombosis prophylaxis and (5) daily oral care with chlorhexidine. While all VAP preventive approaches were continued to be applied on routine in uncontrolled phase, the 5 approaches corresponding to study approaches were carried out under control. For this reason, before the initiation of the study, doctors and nurses working at ICU were informed at a briefing about the approaches that are included in the re-designed ventilator bundle. This briefing was done again when a new staff is included into the ICU team or when was needed.

VAP-PBAL forms were filled in by doctors and nurses who are giving the routine care and treatment to the patients in intensive care unit at each shift (08:00-16:00, 16:00-24:00, 24:00-08:00). VAP-PBCL forms were filled in by chief the doctor and nurse in charge of evaluation of the study at 08:30-09:00 upon visiting the patients included into the study after checking the VAP-PBAL forms.

VAP development conditions data and the day of VAP beginning of patients who were observed during controlled and uncontrolled phases, was gathered from Hospital Infection Control Committee records. The pneumonia that occurred with patients who were mechanically ventilated with intubation for longer than 48 hours in intensive care unit, diagnosed by infectious diseases specialist of research team according to clinical, laboratory and radiological symptoms.

Ethics of the Study

Before the initiation of the study, Sivas Cumhuriyet University, Faculty of Medicine’s Clinical Studies Ethics Committee’s approval (Resolution Number: 2016-12/17) was taken and written permission of Sivas Cumhuriyet University, Healthcare Research Hospital’s Anesthesiology and Reanimation Department’s Intensive Care Unit, was taken. Upon informing the participant patients and their relatives, and taking written permission form them, the data was gathered by research team. The patients and their relatives were informed that, participating to the study is totally up to them, their names will be written on data gathering forms but their personal information will only be used in this study and will stay classified.

Evaluation of the Data

Gathered data was evaluated through SPSS 22 software and it was presented in numbers, percentages, averages and standard deviations. The data was analyzed via Kolmogorov Smirnov test and it was determined that the data does not correspond to standard range. For this reason, in order to match the non-parametric test assumptions, chi square test, Mann-Whitney U and Kruskal Wallis tests were utilized. Margin of error (α) was 005.

Table 1: Distribution of controlled and uncontrolled group patients according to introductory features.

Int J Nurs Clin Pract
ISSN: 2394-4978
Volume 5. 2018. 296

Findings

It was determined that average age of the patients of uncontrolled group was $X=70.41\pm15.63$, 60.8% were males and 66.7% of them were diagnosed with respiratory insufficiency. Average age of the patients in the controlled group was $X=69.51\pm18.18$, 76.7% of them were males and 60.5% of them were diagnosed with respiratory insufficiency. 60.5% of this group were transferred from other departments and 74.4% of them were hospitalized because of internal diseases. Average age of the patients of uncontrolled group was $X=69.51\pm18.18$, 76.7% of them were males and 60.5% of them were diagnosed with respiratory insufficiency. It was also seen that the number of days spent on mechanical ventilation by uncontrolled and controlled groups was highly meaningful in statistical terms ($p=0.035$). With the uncontrolled group while the number of VAP development days on average was $X=27.52\pm34.03$, $X=11.20\pm12.34$ respectively and the difference was statistically very meaningful ($p=0.001$) (Table 2).

When we analyze application of the ventilator bundle approaches according to shifts; it was seen that doctors and nurses elevated the bedhead around 30°-45° and did daily oral care with chlorhexidine without 100% adaptation. Daily sedation evaluation and peptic ulcer prophylaxis approaches were conducted at a rate of 100% at 08.00-16.00 shift but the rate decreased at other shifts. The least followed ventilator bundle approach was deep vein thrombosis prophylaxis and the application rates for 08.00-16.00, 16.00-24.00 and 24.00-08.00 were 97.7%, 14% and 7% respectively (Table 3).

In our study, it was found out that the adaptation level of doctors and nurses working in intensive care unit at 08.00-16.00, 16.00-24.00 and 24.00-08.00 is 99.54%, 65.02% and 45.12% respectively. The adaptation rate of ICU staff was 100% for elevation of the bedhead around 30°-45°, and daily oral care with chlorhexidine; and adaptation rates for daily sedation evaluation approach, peptic ulcer prophylaxis approach and deep vein thrombosis prophylaxis approach were 41.86%, 68.03% and 39.56% respectively. Evaluating this data, it was calculated that the total adaptation level of doctors and nurses of ICU was 69.89% (Table 4).

When the VAP development condition was analyzed according to introductory features among controlled and uncontrolled groups, no statistically meaningful correlation was found ($p=0.05$) (Table 5).

Discussion

Though it is stated in the literature that ventilator bundle applications are effective in reducing VAP development speed [1,3,9,27], it is also emphasized that in order to achieve significant reductions in VAP development speed, the adaptation level to the ventilator bundle must be 95% or over [16,28]. In this context, although the general adaptation rate to the ventilator bundle with the controlled group (69.89%) (Table 4) is rather lower than the level recommended in the literature, while the VAP rate (19.6%) and VAP speed (7.12/1000)

Table 3: Doctors’ and Nurses’ distribution of ventilator bundle approaches application rates according to shifts.
was significantly and statistically fewer (p<0.05) with the controlled group and ventilator bundle adaptation control reduces VAP development by 75%. Reading the related literature, it can be seen that there are a lot of studies that supports our study; and these studies show that with proper application of ventilator bundles [4,12,14,15,19-26,29-35] and higher adaptation of the staff to them [14,15,18,20,23,24,26,31-38] VAP rate and speed decreases. However, diversely from our study, ventilator application bundles of different approaches and various numbers of them were utilized in those studies [4,12,14,15,19-26,29-35] and bundles were mostly applied by nurses [19-26]. Yet, it is of high significance to utilize the scientifically proven up-to-date ventilator bundle applications by multi-discipliner teams. In this context, the five approaches ventilator bundle, which was updated by IHI, was applied by a multi-discipliner team within our study, and relatively high success was achieved on VAP development rate and decreasing the incidence rate via bundle applications and bundle adaptation control processes.

The preventive methods applied to patients, who are staying at ICUs on mechanical ventilators, is very important, and the two most important indicator of effectiveness of treatment and care are number of the days spent at hospital and number of days spent on mechanical ventilation. In this context, throughout the study it was found out that, in giving effective and efficient healthcare VAP preventive bundles are vitally required and of high importance.

The ventilation bundles, which include some approaches of vital importance and help to achieve success when applied totally, are becoming more and more important and recommended more often in national and international guidelines. In this context, when the application adaptation of doctors and nurses was inspected according to their shifts we saw that; 30°-45° elevation of bedheads and daily oral care with chlorhexidine applications were conducted at the rate of 100%, daily sedation evaluation and peptic ulcer prophylaxis approaches were done at the rate of 100% at 08.00-16.00 shift and the rate for these two approaches declined at other shifts. While the application rate was rather high at 08.00-16.00 shift, the rate declined dramatically at evening (14%) and night (7%) shifts, so the lowest rate of application was for deep vein prophylaxis approach (Table 3). Similar studies in the literature show similar results to ours [19,22]. When the methods of these studies are examined, it can be seen that in VAP prevention, ventilator bundle adaptation parameter was taken into consideration. In our study, another parameter is taken into the study of the uncontrolled group of our study is higher, it is determined that the VAP rate (4.7%) and VAP speed (4.14/1000) of controlled group reduced statistically meaningfully (Table 2). In our study, it was proven that VAP development speed was 43% lower with the controlled group and ventilator bundle adaptation control reduces VAP development by 61% (Table 2). Similar studies about this issue responsively showed that VAP speed reduces thanks to ventilator bundle applications and this reduction results in fewer days spent at hospital shorter time periods on mechanical ventilation [4,12,13,19,22,24,26,29,33].

Accordingly, with all these findings, it would not be wrong to state that, in VAP prevention, ventilator bundle adaptation parameter was taken into consideration. In our study, another parameter is taken into the study of the uncontrolled group of our study is higher, it is determined that the VAP rate (4.7%) and VAP speed (4.14/1000) of controlled group reduced statistically meaningfully (Table 2). In our study, it was proven that VAP development speed was 43% lower with the controlled group and ventilator bundle adaptation control reduces VAP development by 61% (Table 2). Similar studies about this issue responsively showed that VAP speed reduces thanks to ventilator bundle applications and this reduction results in fewer days spent at hospital shorter time periods on mechanical ventilation [4,12,13,19,22,24,26,29,33]. Accordingly, with all these findings, it would not be wrong to state that, in giving effective and efficient healthcare VAP preventive bundles are vitally required and of high importance.
equation in order to support and strengthen the ventilator bundle adaptation parameter. Our new parameter is that the doctors and nurses working at ICU for our study, recorded their adaptation level to ventilator bundle application on their own. With this approach, the doctors and nurses were expected to take responsibility in including the ventilator bundle into clinic routines and their awareness level was expected to be increased. In this context, it is obvious that ventilator bundle application rate is pretty high with the staff of 08.00-16.00 shift and the application is included into the routine. However, at evening and night shifts, application rate of especially the deep vein thrombosis prophylaxis approach declined significantly and increasing work load and fewer staff number was speculated to be the reason of this decline.

In all healthcare institutes, application of VAP preventive bundles is at increase but the approaches and numbers included into the bundles differ. Within our study, IHI's updated five approaches bundle was utilized, and it was observed that elevation of bedhead around 30°-45°, and oral care with chlorhexidine approaches were complied with no error (Table 4). Through the literature, it can be seen in similar studies that in ventilator bundle approach the two mentioned above are likely to be the most compliable via application and training [14,23,25]. In parallel with these findings, it is also known that these approaches, which are included in different ventilation bundles and can be fully complied to, are responsibility of nurses. For this reason, non-stop nursing service may result in appropriate application of these approaches.

Conclusion and Recommendations

Within our study, it was found out that the introductory features of controlled and uncontrolled groups were similar. However, while the adaptation rate of controlled group was lower than the average of the literature, and VAP rate and speed was higher with uncontrolled group, it was determined that with the controlled group VAP rate and speed was significantly lower, and this difference is statistically meaningful. In the study, it was determined that the controlled group's, which was inspected by a multi-discipliner team about ventilator bundle application, number of days and the time spent on mechanical ventilation were statistically lower than of the uncontrolled group. At all shifts, it was observed that elevation of bedhead around 30°-45°, and oral care with chlorhexidine approaches were complied with no error, and the least applied approach was deep vein thrombosis prophylaxis. In line with these results, it is thought that the control of the ventilation bundles which were applied to patients had a positive effect on reducing VAP speed and the number of days spent at hospital and recording the ventilation bundle approaches daily by the ICU staff by themselves increased their awareness level about teamwork.

In accordance with our findings (1) application and generalizing of updated ventilator bundles, (2) running regular inspections in order to increase adaptation of staff, (3) strengthening team work in order to increase application and adaptation of ventilator bundles, and (4) increasing number of staffs in order to reduce the workload at evening and night shifts, can be recommended.

Limits

The data gathered through this study is limited to the period when the study was conducted.
